Abstract

Enormous volumes of sediment are produced in the Central Andes and are then delivered into the foreland basins of Amazon basin tributaries. While cosmogenic nuclides in sediment are a suitable tool to measure the denudation rates of sediment-producing areas, the requirement of steady state between nuclide production and nuclide removal by denudation appears to make this method less obvious in depositional foreland basins, where sediment storage may alter $^{10}$Be-based erosion signals from the sediment-providing areas. A published cosmogenic nuclide-based modeling approach however predicts that source-area cosmogenic nuclide concentrations are not modified by temporary sediment storage. We tested this approach in the large Beni foreland basin by measuring cosmogenic $^{10}$Be nuclide concentrations in detrital sediment along a 600 km long floodplain reach. The outcome of our study is that the $^{10}$Be-based denudation rate signal of the Bolivian Andes is preserved in the Beni floodplain even though this basin stores the sediment for thousands of years. For the floodplain part of the Beni basin, the cosmogenic nuclide-derived denudation rate is $0.45 \pm 0.07$ mm/yr, and the respective Andean source area erodes at a very similar rate of $0.37 \pm 0.06$ mm/yr. We thus suggest that any sample collected along a river traversing a floodplain will yield the denudation rate of the source area. This finding opens the unique possibility of constraining paleo-sediment budgets for these large basins using cosmogenic nuclides as the denudation rate signal of the sediment-producing area is preserved in sedimentary archives.

Resumo

O grande volume de sedimento produzido pelas bacias foreland dos Andes Centrais é carregado pelos tributários da bacia do rio Amazonas. Embora os cosmonuclídeos em sedimento constituam uma ferramenta atraente para estimativa da taxa de denudação de áreas-fonte, a exigência da relação inicial entre a produção e a remoção de nuclídeos torna o método menos óbvio no caso de bacias foreland, nas quais o estoque de sedimento pode alterar os sinais de erosão pelo $^{10}$Be das áreas-fonte. Um modelo de nuclídeos cosmogênicos já publicado afirma contudo que a concentração dos nuclídeos não é modificada pelo estoque temporário de sedimento. No presente trabalho esse modelo foi testado na grande bacia foreland de Beni pela medição das concentrações de nuclídeos de $^{10}$Be em sedimento detrítico de um trecho de 600 km ao longo da planície de inundação do rio Beni. Os resultados revelaram que o sinal da taxa de denudação baseada em nuclídeos de $^{10}$Be é preservado nos depósitos da planície de inundação do rio Beni, mesmo em setores onde os sedimentos estejam estocados por milhares de anos. Os valores da taxa de denudação por $^{10}$Be encontrados na planície de inundação e na área fonte foram bastante semelhantes: $0.45 \pm 0.07$ e $0.37 \pm 0.06$ mm/ano respectivamente. Dessa forma sugere-se que qualquer amostra coletada ao longo de tributários que atravessem a planície de inundação fornecerá a taxa de...
erosão da área fonte. Esse resultado antevê a possibilidade de uma redução expressiva na amostragem em estudos que objetivem o cálculo da taxa de denudação baseada em cosmonuclídeos.

1. Introduction

Cosmogenic nuclides in detrital material, especially $^{10}\text{Be}$, have been utilized over the past decade to determine catchment-wide mountain erosion and weathering rates (Bierman and Nichols, 2004; Granger and Riebe, 2007; von Blanckenburg, 2005). It has been found over recent years that even in very complex settings like formerly glaciated basins, cosmogenic nuclides mostly record robust basin-wide denudation rates when compared to long-term denudation metrics measured by fission tracks (Kirchner et al., 2001; Matmon et al., 2003; Wittmann et al., 2007). In this study, we will test whether this method can be employed to infer basin-wide denudation rates from sediment routed through large depositional settings (Bierman and Steig, 1996; Nichols et al., 2005; Nichols et al., 2002). In such basins, sediment is continuously deposited in the floodplain and reincorporated in the active fluvial system by bank erosion. This transient residence in the floodplain with unknown duration may affect cosmogenic nuclide concentrations in such a way that the nuclide concentration that is inherited from the erosion process in the source area may be modified by exposure to cosmic rays in the floodplain or during deep floodplain burial. Wittmann and von Blanckenburg (2009) predicted that despite significant floodplain storage, the denudation signal of the sediment-producing hinterland (e.g. the Bolivian Andes) that is preserved in $^{10}\text{Be}$-nuclide concentrations is not changed over foreland-basin scale distances by using a nuclide budgeting approach. The essentially pristine floodplains of the upper Amazon basin are an ideal test site to test this hypothesis. The cosmogenic nuclide signal of the high Bolivian Andes is well established by a large dataset from Safran et al. (2005). For this area, fission track-derived long-term rates of erosion are also available (Safran et al., 2006). For the ~ 600 km long Beni floodplain, an average residence time for sediment is ~ 5 kyrs as measured from U-series by Dosseto et al. (2006). We will show here that it is indeed possible to calculate meaningful catchment-wide denudation rates for the hinterland in large depositional basins, and we do so by providing new cosmogenic nuclide concentrations from Beni River floodplain sediment.

2. Geology, geomorphology and climate

One major Amazon foreland basin to the Andean orogenic belt is the Madeira basin, which comprises the Beni (~300,000 km$^2$) and the adjacent Mamoré basin (~600,000 km$^2$; see Figure 1). With an annual discharge exceeding 32,000 m$^3$/s at its confluence with the Amazon, and an average suspended sediment load of > 400 Mt/yr (Wittmann et al., 2011), the Madeira ranks the fourth to fifth largest river in the world (Latrubesse, 2008; Latrubesse et al., 2005) and thus is one of the largest sediment-delivering rivers to the Amazon River (Guyot et al., 1996). In the Madeira basin upstream of Porto Velho (see Figure 1), three major morpho-structural units are present: The Bolivian segment of the Andes at average elevations of ~ 2000 m, the Amazon plain featuring vast flooded areas at altitudes < 200 m; and the subdued topography of the Brazilian shield featuring elevations of ~ 400 m, constituting old Precambrian rocks (outcropping only in lower Mamoré areas). The transition of the sediment-producing Andean areas to the depositional floodplain setting is located at the city of Rurrenabaque; downstream in the floodplain part to the confluence with the Mamoré River at Cachuela Esperanza (see Figure 1), the Beni River has two large tributaries, the Madre de Dios River at Miraflores draining the Peruvian and Bolivian Andes, and the Orthón River, a tributary exclusively draining Miocene lowland sediments of the Fitzcarrald Arch formation (Espurt et al., 2007). Beni River channel migration rates average at ~ 15 m/yr (Aalto, 2002a), with meander-bend migration rates up to ~ 30 m/yr (Gautier et al., 2007), accounting for rapid sediment exchange between the floodplain and the mainstream. Regarding the floodplain setting of the Beni, Platker (1964) was the first to point out that the Beni River channel experienced successive counterclockwise shifts from SE to NW. The river course evidently adjusted to basinial uplift located in the area south of Puerto Siles, with remnant structures (i.e. underfit streams, oxbow lakes) still present in the area east of the modern channel (see Dumont, 1996, for details). Simultaneously to the counterclockwise shifting, Dumont (1996) suggested that the deflection point (i.e. the point where the Beni River leaves the piedmont and enters the floodplain) shifted northward, potentially resulting in changes in Andean drainage area upstream of the floodplain. The timing of these changes has not been pinned down with modern dating techniques and only indirect methods are available; for example, Dumont (1996) correlates remnant channel structures of the two earliest shifts to periods of lower discharge than today and thus these channels may represent the active Beni River during last Holocene dry phase (Dumont, 1996). Various paleoclimatic evidence from the Central Andes suggests that the mid-Holocene (~8 to ~ 5-4 kyr before present,” B.P.”) underwent a major phase of aridity with very low rates of precipitation (e.g. Cross et al., 2000; Rowe, 2002; Tapia et al., 2003). This emplacement to the mid-Holocene period enables a very tentative time frame for the shift of the paleo-Beni River following the interpretation of Dumont (1996). Within
the remaining Holocene period until today, the Central Andes probably experienced a wetter climate similar to today’s (Abbott et al., 2003; Tapia et al., 2003).

3. Methods
3.1 Cosmogenic nuclide sampling and analytical techniques

Our cosmogenic nuclide sampling of sediment from active fluvial bars was carried out near a gauging monitoring station where possible (see Figure 1). All samples were collected by J.L. Guyot within the framework of the HYBAM project. The upper Andean Beni basin is characterized by sample BE 1 at Rurrenabaque. In the Beni floodplain, our sampling transect covers a distance across the floodplain of about 600 km from Rurrenabaque to Cachuela Esperanza (samples BE 2 to 17). Tributary input to the Beni is characterized by samples from the rivers Madre de Dios at Miraflorres (MD 15), and the Orthón at Caracoles (OR 16). The lower Mamoré floodplain was sampled at Guayaramerin (Mar 18). The latter sample integrates over the cratonic areas of the Brazilian Shield (~ 50% floodplain area; ~ 60% Brazilian Shield area; ~ 10% Andean territory). The Madeira River was sampled at about ~ 40 km below the Beni-Mamoré confluence (Mad 19) and again at Porto Velho (Mad 20).

Pure quartz of grain sizes between 125 and 500 µm was selected for 10Be analysis after drying, sieving, magnetic separation and selective leaching with hydrofluoric acid (5%). 10Be was extracted from purified quartz using standard methods (von Blanckenburg et al., 2004); 10Be/9Be ratios were measured with accelerator mass spectrometry at ETH Zurich relative to a standard with a nominal value of 10Be/9Be = 95.5 × 10−12, which is based on a 10Be half life of 1.51 Myr (Hofmann et al., 1987). Up to 300 µg of 9Be carrier was added to each sample; 10Be/9Be ratios are given in Table 1. Analytical as well as blank error corrections are described in Table 1. Calculations of production rates, using pixel-based altitudes from 1 km resolution SRTM-DEM, and attenuation laws including muons were done following Schaller et al. (2002); atmospheric scaling was done following Dunai (2000). As a sea level high latitude (SLHL) reference production rate we used a value of 5.53 at/g (Qz) (Kubik et al., 1998). Published denudation rates from the high Andes of the Andean Beni basin by Safran et al. (2005) were recalculated for comparison with our dataset; we have recalculated their denudation rates for Dunais’ atmospheric scaling laws and included nuclide production by muons as suggested by Schaller et al. (2002). A revised dataset, calculated with a revised 10Be half-life (Chmeleff et al., 2010), reduced 10Be/9Be ratios according to Kubik and Christl (2010) to allow for direct comparison with new AMS standards, and newly-revised lower reference production rates (e.g. Fenton et al., 2011), can be obtained from the author upon request.

4. Cosmogenic 10Be nuclide concentration results

Nuclide concentrations of 10Be have been measured over distances of 800 km along the river course at various points from Rurrenabaque to Porto Velho (see Figure 1). 10Be nuclide concentrations for the Andean Beni trunk stream at Rurrenabaque at the upper Beni basin outlet are 3.8 ± 0.6×104 at/g(Qz) (average of Be 1a and b with one sigma uncertainty, where in this study “a” denotes the 125-250 µm and “b” the 250-500 µm grain size fraction; see Table 1). The centerpiece of this study are 12 samples (Be 2 to 17, including replicates and grain sizes, excluding tributaries), taken along the Beni trunk stream downstream of Rurrenabaque to Cachuela Esperanza. The average nuclide concentration from the 12 trunk stream samples upstream of the Beni-Mamoré confluence is 3.7 ± 0.5×104 at/g(Qz) (stating one sigma uncertainty, see Table 1, Figure 2). Variability within measured nuclide concentration is however higher as indicated by a standard deviation of 3.7 ± 1.6×104 at/g(Qz).

Tributary input to the Beni is characterized by samples from the rivers Madre de Dios at Miraflorres (Be 15a), and the Orthón at Caracoles (Be 16b). The cosmogenic nuclide concentration of the Madre de Dios (2.1 ± 1.0×104 at/g(Qz), see Table 1) is comparable with the Beni at their confluence; the Orthón Rivers’ nuclide concentration is with 11.1 ± 1.1×104 at/g(Qz) (see Table 1) clearly distinct from that carried by the Beni River. Sample Mar 18 characterizes the lower Mamoré at Guayaramerin, yielding an average of 4.9 ± 1.7×104 at/g(Qz) for the two grain sizes (see Table 1). This river drains ~60% old cratonic shield areas (Guaporé River) and ~40% Andean territory (upper Mamoré River). The Madeira river samples Mad 19a (nuclide concentration is 4.0 ± 0.5×104 at/g(Qz)) and Mad 20a (3.5 ± 0.4×104 at/g(Qz); see Table 1) integrate over the entire Madeira River basin including the Beni and Mamoré.

5. Cosmogenic nuclide budgeting of floodplain sediment transfer in the Beni River

The transfer and storage of sediment through a large lowland basin may provide bias on the concentration of cosmogenic nuclides, because cosmogenic nuclide concentrations may be prone to additional irradiation or decay during storage and shielding in floodplain systems. However, we have shown in section 4 that the Beni
flux (\(\approx 210 \text{ Mt/yr}\)) as well as fluxes from point bar re-deposition (200 Mt/yr). Both are identical to the total annual flux passed on from the sediment-producing areas, the Andes, to the floodplain (210 Mt/yr). Standard concentration Cup of 38000 at/g(Qz) (average from Be 1a and 1b), an ingoing sediment flux of 200 Mt/yr (average model runs were performed using parameters representative of the natural Beni system, such as a starting nuclide Beni, this assumption has been validated by Aalto et al. (2002), who have measured the Beni cutbank erosion mixed material. The model assumes steady-state between river bank erosion and point bar deposition. For the directly from the previous reach. Sediment deposition is simulated by forming point bars from portions of the sediment eroded from the river bank as the river migrates by meandering. In detail, our model assumes erosion of sediment from river cut banks due to lateral bankfull migration, and an admixture of sediment conveyed directly from the previous reach. Sediment deposition is simulated by forming point bars from portions of the mixed material. The model assumes steady-state between river bank erosion and point bar deposition. For the Beni, this assumption has been validated by Aalto et al. (2002), who have measured the Beni cutbank erosion flux (\(\approx 210 \text{ Mt/yr}\)) as well as fluxes from point bar re-deposition (200 Mt/yr). Both are identical to the total annual flux passed on from the sediment-producing areas, the Andes, to the floodplain (210 Mt/yr). Standard model runs were performed using parameters representative of the natural Beni system, such as a starting nuclide concentration Cup of 38000 at/g(Qz) (average from Be 1a and 1b), an ingoing sediment flux of 200 Mt/yr (average sediment flux at Rurrenabaque), and an average channel depth of 20 m, which estimates floodplain storage depth (Wittmann and von Blanckenburg, 2009). Within these standard runs, an increase in \(^{10}\text{Be}\) nuclide concentrations across the floodplain of only 0.6%, relative to Cup, was detected. We then tested these boundary conditions of the input parameters to changes in climate and erosion. For example, the sediment flux from the Andes was decreased by four orders of magnitude while keeping Cup constant, as this would be the case during increased aridity in the source areas. A four-fold decrease in channel depth was tested, as during phases of increased precipitation and runoff the river may scour and increase its channel depth. This would result in admixing of less irradiated material to the sediment carried in the main channel. Increasing the estimated average sediment storage time (4-6 kyr) by 10-fold (to 40-60 kyr), a longer-term storage of sediment in the floodplain was tested. The latter test can be seen as an upper-limit test for the successive channel shifting of the Beni River through its floodplain during the Holocene. This 10-fold increase in sediment storage time causes \(^{10}\text{Be}\) nuclides to accumulate by only 5.8% over Beni River floodplain distances (relative to Cup). All other tests showed even less relative nuclide accumulation. Decay of nuclide concentrations (i.e. resulting in decreased concentrations across the floodplain) was only observed when model runs were performed with shorter-lived nuclides other than \(^{10}\text{Be}\), such as in situ-produced \(^{14}\text{C}\) (half-life of 5730 yr), or when storage times of sediment in the floodplain exceeded the half-life of \(^{10}\text{Be}\) (newly determined to be 1.39 Myr, (Chmeleff et al., 2010)).

The model outcomes demonstrated here and in more detail in Wittmann and von Blanckenburg (2009) show that under most conditions encountered in nature, initial nuclide concentrations of the Andean source area are not modified by floodplain processes. Sediment storage times are usually too short when compared to the long half-life of \(^{10}\text{Be}\), and floodplain storage depths are too shallow to modify nuclide concentrations from shielding and decay when buried. Overall, the Andean erosion signal is preserved throughout transfer of sediment through the floodplain. These results are supported by a more sophisticated numerical reach-scale theory model by Lauer and Willenbring (2011), who also conclude that only relatively modest down-channel changes in the concentration of long-lived nuclides occur.

With regard to our observed scatter in nuclide concentrations along the Beni floodplain (see Section 4), however, we suggest that changes in the erosion rate of the source-areas itself (which would correspond to changing Cup in our model) cause these variations in nuclide concentrations. Similarly, as the deflection point of the piedmont-lowland transition might have changed in response to basinal uplift, changes in the size of the Andean sediment-providing drainage basin might have comparable effects.

### 6. Prerequisites for the calculation of denudation rates in depositional basins

The denudation signal of the sediment source area is preserved by its cosmogenic nuclide concentration, regardless of the duration of temporary storage. This conclusion is drawn from the model presented by Wittmann and von Blanckenburg (2009) and has validity if the storage is short compared to the half life of the nuclide (see Section 5). However, the calculation of a cosmogenic nuclide-derived denudation rate \((\varepsilon_{\text{cosmo}})\) that integrates over floodplain area requires scaling of the nuclide production rate to the altitude of the sediment producing area, because within a floodplain, sediment is not actively being produced. We therefore calculated floodplain-corrected cosmogenic nuclide-based denudation rates (termed \(\varepsilon_{\text{FC}}\) in the following) (Wittmann and von Blanckenburg, 2009) by defining a “floodplain-corrected” sediment source area \(A_{\text{FC}}\) for all basins that contain a portion of floodplain area. \(A_{\text{FC}}\) excludes lowland area where sediment is mostly deposited. For the Beni basin,
this transition of the sediment-producing regime and that of mostly sediment deposition in the floodplain is
located at the city of Rurrenabaque. We then proceeded to calculate an average SRTM pixel-based floodplain-
corrected cosmogenic production rate ($P_{FC}$) that is limited to the area contributing sediment in the respective
basin (see Table 1). Solving Lal’s (1991) equation for a uniform floodplain-corrected denudation rate $\varepsilon_{FC}$
(mm/yr), one obtains the following simplified equation:

$$\varepsilon_{FC} = \left( \frac{P_{FC}}{\rho \times C} - \lambda \right) \times \Lambda$$

(1)

where for simplicity the equation is shown with $P_{FC}$ containing all nucleogenic and muonic production
mechanisms. $C$ gives the nuclide concentration (at/g(Qz)) in the sample, $\lambda$ is the decay constant (1/yr), $\Lambda$ is a mean
cosmic ray attenuation length (g/cm²) including nucleons and muons, and $\rho$ is the density of rock (g/cm³).

6.2 Gauging-derived sediment yields in the Beni basin and their treatment

For the Beni basin and the Mamoré at Guayaramerin, modern denudation rates from sediment gauging
and dissolved element measurements are available for several decades (Table 2). In large lowland basins, sediment
yields (termed $F_{M}$ in the following, and calculated by taking the measured $Q_{M}$ (t/yr) of a basin divided
by $A_{basin}$ (km²)) decrease with increasing basin size if no new sediment is added downstream (e.g. Hovius, 1998;
Milliman and Meade, 1983; Milliman and Syvitski, 1992). This effect arises even if no sediment is deposited in
the floodplain and the sediment discharge $Q_{M}$ is uniform throughout the floodplain. If the sediment yield is used
to calculate denudation rates of the areas actually producing sediment, a correction of this effect is necessary.
Thus, published gauging-derived sediment yields $F_{M}$ (see Table 2) were corrected for floodplain area according
to:

$$F_{FC} = \frac{Q_{M}}{A_{FC}}$$

(2)

where $F_{FC}$ is the floodplain-corrected sediment yield of a basin (see Table 2), and $A_{FC}$ is the sediment-producing
area which is determined as described in Section 6 for cosmogenic nuclide production rates. We term “modern”
denudation rates calculated from sediment yields $\varepsilon_{M}$, and floodplain-corrected modern denudation rates $\varepsilon_{MFC}$.

The total sediment load that is discharged from the Andes to the Beni floodplain passing Rurrenabaque
amounts to 220 Mt/yr (Guyot et al., 1996) (see Table 2), which corresponds to a modern denudation rate range of
1.18 mm/yr. At Riberalta (RIB, see Figure 1) gauging station, this flux decreases strongly to ~120 Mt/yr
(corresponds to an $\varepsilon_{MFC}$ of 0.71 mm/yr, see Table 2), indicating net sediment deposition. At Cachuela Esperanza
downstream of the Orthón and Madre de Dios confluences, $\varepsilon_{MFC}$ is with 1.15 mm/yr again in the same range as at
Rurrenabaque; this increase is attributed to the high sediment input from the Madre de Dios River. At the outlet
of the Mamoré floodplain at Guyaramerin, a total sediment flux of ~80 Mt/yr is recorded, which corresponds to a
denudation rate $\varepsilon_{MFC}$ of 0.25 mm/yr.

7. Cosmogenic $^{10}$Be-derived denudation rates and their interpretation

7.1 Denudation rates of the sediment-producing upper Andean Beni basin

Measured cosmogenic $^{10}$Be-derived denudation rates $\varepsilon_{cosmo}$ result in an average denudation rate of 0.37 ±
0.06 mm/yr from samples BE 1a and 1b (see Table 1, Figure 3) at the transition from the Andes to the floodplain.
This denudation rate should average over the entire upper Beni basin, including the high Andes and Piedmont
section. At the same location, Safran et al. (2005) have determined a cosmogenic nuclide-based denudation rate
of 0.55 ± 0.03 mm/yr (recalculated from sample BOL-50, Safran et al. (2005)). The observed difference results
from different nuclide concentrations when taking the same production rate for denudation rate calculation
and can potentially be attributed to temporal variability of source areas providing sediment. For example, Safran
et al. (2005) have sampled in June 1998, at the end of the flood period, while samples for this study have been
taken in October 2002, during the low water stage. The higher denudation rate measured at Rurrenabaque by
Safran et al. (2005) might be indirectly induced by a stronger ENSO event during the sampled year, producing
large landslides in the Piedmont region at elevations below 3000 m (Blodgett and Isaacks, 2007). Our sampling
year 2002, was, in terms of the southern oscillation, a normal year. The beginning of 1998 during which Safran
et al. sampled was influenced by a strong El Niño phenomenon, and the end of the year was influenced by a
moderately strong La Niña (Romero et al., 2007). Thus, lower the nuclide concentration measured at
Rurrenabaque by Safran et al. (2005) might be indirectly induced by a stronger ENSO event during the sampled
year, producing large landslides in the Piedmont region.
In addition to temporal variations, we cannot exclude the possibility of spatial variations in erosion sources in the Bolivian Andes. For example, stream sediment in the upper Beni basin can vary in the mixing proportions of sediment sourced in the high-relief, steeply sloped Andean part and the low-relief Piedmont section. For the Piedmont region, no $\epsilon_{\text{cosmo}}$ data is available. The dataset from Safran et al. (2005) documents the high spatial variability of denudation rates present in the high Bolivian Andes; the mean denudation rate amounts to 0.36 mm/yr with a standard deviation of 0.22 mm/yr. The flux-weighted mean for this area amounts to $0.43 \pm 0.03$ mm/yr, which compares reasonably well to our denudation rate measured at Rurrenabaque (see Figure 3).

Denudation rates derived from fission-track analyses in the upper Beni basin integrate over long time scales from 5 to 20 Myr and the observed rates are with 0.2 - 0.6 mm/yr (average $\sim 0.3$ mm/yr) in the range of cosmogenic nuclide-derived denudation rates (Safran et al., 2006). An exponential increase in exhumation rate at 10 - 15 Myr from 0.2 to $\sim 0.7$ mm/yr has also been suggested for this area by Benjamin et al. (1978) and Anders et al. (2002).

7.2 Denudation rates of the Beni River floodplain

From our $^{10}\text{Be}$ nuclide concentrations obtained in Section 4, we recalculated the denudation rates for the Beni River floodplain according to Section 6 to include the sediment-producing areas only ($\epsilon_{\text{FC}}$, see Eq. 1) following Wittmann and von Blanckenburg (2009). Results from this recalculation give an average floodplain denudation rate $\epsilon_{\text{FC}}$ of $0.45 \pm 0.06$ mm/yr (all uncertainties one sigma) that is very similar to our Andean denudation rate estimate at Rurrenabaque ($0.37 \pm 0.06$ mm/yr), and to the average rate of $0.55 \pm 0.03$ mm/yr at Rurrenabaque determined by Safran et al. (2005).

The denudation rate for the Madeira basin, which includes the Beni and Mamoré basins, amounts to $0.28 \pm 0.04$ mm/yr from samples Mad 19 and Mad 20 ($n = 3$). This rate is lower than average Andean rate derived from the mean Beni denudation rate at Rurrenabaque ($0.37 \pm 0.06$ mm/yr). This decrease is probably caused by high-nuclide concentration input from the Guaporé basin, which is demonstrated by higher mean nuclide concentrations for samples Mar 18a (see Table 1). The Guaporé River mostly drains the Brazilian shield, an area of high long-term geomorphic stability featuring old Precambrian rocks that evidently erode at very slow rates (Wittmann et al., 2011).

8. Discussion

8.1 Cosmogenic nuclide-derived denudation rates compared to published gauging-derived rates

Sediment-gauging derived denudation rates ($\epsilon_{\text{MFC}}$) for the Beni floodplain are with a mean rate of $\sim 1$ mm/yr (Table 2) significantly higher than the mean cosmogenic nuclide-derived rate ($\epsilon_{\text{FC}} = 0.45$ mm/yr). This difference is probably due to the different integration time scales of both methods. Our cosmogenic nuclide measurements record the time-integrated signal of denudation for the last $\sim 2.4$ kyr in the Beni, whereas sediment gauging data integrates over the gauging period, which is typically $\sim 10$ yr (see Table 2). An increase in modern denudation rates can be attributed to changes in land use (Vanacker et al., 2007) or climate (e.g. Cross et al., 2000) in the sediment-providing area. For example, the mid-Holocene period in the Central Andes is characterized by aridity (see Section 2), with levels of Lake Titicaca being $\sim 100$ m lower than today. The final termination of the arid phase is being discussed, but occurred at the latest around 1.5 kyr (Tapia et al., 2003). In this case our new cosmogenic nuclide-derived denudation rates would integrate over a drier climatic phase than today, which could result in the offset between higher modern and lower long-term erosion rates.

8.2 The temporal and spatial scales in denudation and their extension to floodplain settings

A summary of all cosmogenic nuclide-derived denudation rate data for specific regions in the Madeira basin, also including the Mamoré basin, is given in Figure 4 (Wittmann et al., 2009). In the following, we will discuss the significance of the observed erosion patterns in terms of more general issues, e.g. (1) temporal uniformity in denudation, and (2) the observation that the spatial scale of cosmogenic-derived denudation meters from the source area may be extended to depositional floodplain settings. (1) Long-term denudation rates derived from fission-track analyses are very similar to the cosmogenic nuclide-derived denudation rates in the upper Beni basin. This finding is surprising, given that the Holocene period over which cosmogenic nuclides record denudation is not necessarily representative for the Quaternary and Pliocene climate over which fission tracks operate. Yet this observation has been made elsewhere (Kirchner et al., 2001; Matmon et al., 2003; Wittmann et al., 2007) for very different settings in terms of climatic and tectonic boundary conditions. (2) Denudation rates recorded by cosmogenic nuclides are subjected to strong spatial scatter in the high Andes of the Beni basin (see Section 7.1). This scatter is only to some extent preserved in lowland nuclide concentrations; the overall variability in lowland nuclide concentrations is much lower than the variability observed in the source area (see Figure 5). With increasing basin size, this observed scatter seems to be averaged out, and average denudation
rates are similar for all basin sizes. For Andean basins < 1000 km², flux-weighted denudation rates average 0.47 ± 0.03 mm/yr and to 0.42 ± 0.03 mm/yr for basins between 1000 - 11,000 km², respectively. Floodplain basins > 70,000 to ~ 300,000 km² average to 0.45 ± 0.06 mm/yr ($\epsilon_{FC}$, samples BE 2 to 17). This signal is again similar to the long-term erosional signal of ~ 0.3 mm/yr from fission tracks. An explanation for this uniformity may lie in the ability of the floodplain to buffer against changing sediment supply discharged from the source area (Métivier and Gaudemer, 1999). Continuous storage and remobilization of alluvium via lateral channel migration in the floodplain apparently damps effects from changing sediment supply caused by climatic or tectonic perturbations.

9. Conclusions

This study shows that denudation rates measured from cosmogenic nuclide concentrations in the floodplain of the Beni basin (Bolivia) are, within a variability expected of high-relief areas that tend to erode stochastically, identical to those obtained from the sediment-providing Bolivian Andes. Cosmogenic nuclide concentrations in the floodplain are not altered by storage of sediment that is longer than the integration times of the cosmogenic nuclide method. In addition, the large variability in Andean denudation rates does not transfer to the floodplain setting where we notice very small variability in cosmogenic nuclide-derived denudation rates. This indicates that denudation rates converge to a spatially-averaged erosion signal in the lowlands. When compared to long-term estimates of erosion, cosmogenic nuclide-derived denudation rates in the floodplain resemble those from Andean fission track analysis. These findings allow the suggestion that cosmogenic nuclides are the method of choice for tracing denudation rate signals over large floodplain distances. Denudation rates of the sediment-producing areas are being conserved as spatially and temporally averaged signals, and short-term spatial or temporal changes are dampened-out. In such large depositional basins, the denudation signal from the sediment-providing area is not only preserved, but also will a sample collected at any point along the river course from within the active floodplain channel yield an average denudation rate of the source area.

Figures

Figure 1) Detailed topographic map and fluvial network of the Beni River basin with sampling points for cosmogenic $^{10}$Be (black triangles). Sediment gauging stations (white stars) operated by HYBAM are abbreviated as in Guyot et al. (1996). Where cosmogenic samples were taken at the same location as a gauging station, the sample name is indicated below the HYBAM gauging station code.
Figure 2) Cosmogenic nuclide concentration profile for the Beni (black circles) and Madeira River (grey circles with black dot) plotted against distance from transition between Andes and the floodplain at Rurrenabaque (km) with sample IDs (see Figure 1, Table 1) given at the bottom. Grey circles denote tributary samples. Right axis gives elevation of idealized topographic profile of the basin (m), which has been projected from several valley-perpendicular profiles into a single plane. Andean nuclide concentrations and nuclide concentration at Rurrenabaque (BOL-50) measured by Safran et al. (2005) are shown as white circles.

Figure 3) Basin-averaged denudation rates for the Beni River floodplain, calculated using the production rate relevant to each sampling points’ basin hypsometry (white circles; left axis) from Rurrenabaque to Porto Velho. Using a hinterland production rate of 15.3 at/g(O2)/yr, the cosmogenic denudation rates of the Beni River floodplain were recalculated according to Eq. 1 (grey circles). The rivers Madre de Dios, Orthón, and Mamoré (samples BE 15a, OR16b, and Mar 18) are not included, because their basins integrate over different Andean source areas and thus have different starting production rates. Denudation rates for the Madeira river samples (Mad 19a and Mad 20 at 570 km and 800 km, respectively) have been calculated using a production rate of 12.9 at/g(O2)/yr. White squares show sediment yield data from gauging stations (right axis; from Guyot et al. (1996)), which also have been recalculated with the surface area of the sediment-providing area of $6.8 \times 10^4$ km$^2$ at Rurrenabaque according to Eq. 2 (grey squares), except at PVL on the Madeira River, where the total Andean area is $26 \times 10^5$ km$^2$. Sediment yield was calculated from erosion rates using a density of 2.7 g/cm$^3$ and thus, right and left axis scale linearly. Typical error bars for both methods are also given. Vertical dashed lines denote the flux-weighted Andean mean from Safran et al. (2005). For abbreviations, see Figure 1.
Figure 4) Cosmogenic nuclide-derived denudation rates (mm/yr) for tributaries of the Madeira basin including the Beni, Mamoré and Guaporé basins (Wittmann et al., 2009), of which their outlets are marked by black stars. The Beni basin is subdivided into its major tributaries of Orthón and Madre de Dios as well as the upper Andean part of the basin, for which an average denudation rate from sample BE 1 is given as well as the weighted mean recalculated from Safran et al. (2005). The Andean Mamoré basin includes the small Maniqui catchment and more southern Andean Mamoré samples of the Grande, Pirai, Ichilo, and Chaparé Rivers. The floodplain part of the Ichilo basin is indicated by the dashed line. An average denudation rate for the Brazilian Shield (~0.02 mm/yr) has been taken from Wittmann (2008). Figure reprinted from “From source to sink: Preserving the cosmogenic 10Be-derived denudation rate signal of the Bolivian Andes in sediment of the Beni and Mamoré foreland Basins”, Vol. 288 by Wittmann et al., page 472, with permission from Elsevier.

Figure 5) Denudation rates (with one sigma errors) for the Madeira basin at Porto Velho plotted against drainage area. Andean cosmogenic nuclide data is recalculated from Safran et al. (2005). Floodplain rates are corrected for decrease in production rate across low-elevation floodplain areas according to Eq. 1. The data shows that with increasing basin area, the spread in denudation rate decreases, and that the cosmogenic sample taken at 1.000.000 km² (Porto Velho) is similar to the Andean mean rate from Safran et al. (2005). The difference to the Andean average is in this case attributed to sediment input high in nuclide concentration from the slowly eroding parts of the Guaporé basin. Figure reprinted from “From source to sink: Preserving the cosmogenic 10Be-derived denudation rate signal of the Bolivian Andes in sediment of the Beni and Mamoré foreland Basins”, Vol. 288 by Wittmann et al., page 473, with permission from Elsevier.
